| 16. Abstract The objective of this investigation was to evaluate three different battery analytical models for predicting electric vehicle battery output and the corresponding electric vehicle range for various driving cycles as described by SAE-J227a. The approach consisted of using the models to predict output and range, then comparing the results with experimentally determined values. The latter were determined by laboratory tests on batteries, using discharge cycles identical to those encountered by an actual electric vehicle while on the SAE cycles. Results indicated that the so-called Modified Hoxie Model gave the best predictions with an accuracy of about 97-98% in most cases and 86% in the worst case. Solution of this model required lengthy iterative calculations that were carried out with a computer. The program that was written to perform these calculations is included in this report. Also described are the program and hardware that were used to automatically discharge the battery in accord with the current profiles corresponding to the SAE driving cycles. Future effects are recommended using these models to predict the effect of battery type on range of a wide variety of vehicles. | | | |

PREFACE

The work described in this report was performed by the Control and Energy Conversion Division of the Jet Propulsion Laboratory.

ACKNOWLEDGEMENT

We would like to acknowledge the assistance of Mr. Fred Akers in setting up the computer program for solving the battery model. We would also like to acknowledge the helpful discussions with Mr. W. Rippel for his support of this effort.

ABSTRACT

The objective of this investigation was to evaluate three different battery analytical models for predicting electric vehicle battery output and the corresponding electric vehicle range for various driving cycles as described by SAE-J227a. The approach consisted of using the models to predict output and range, then comparing the results with experimentally determined values. The latter were determined by laboratory tests on batteries, using discharge cycles identical to those encountered by an actual electric vehicle while on the SAE cycles. Results indicated that the so-called Modified Hoxie Model gave the best predictions with an accuracy of about 97-98% in most cases and 86% in the worst case. Solution of this model required lengthy iterative calculations that were carried out with a computer. The program that was written to perform these calculations is included in this report. Also described are the program and hardware that were used to automatically discharge the battery in accord with the current profiles corresponding to the SAE driving cycles. Future efforts are recommended using these models to predict the effect of battery type on range of a wide variety of vehicles.

SECTION I INTRODUCTION

Public Law 94-413, the Electric and Hybrid Research, Development, and Demonstration Act of 1976, authorizes a broad program designed to promote electric and hybrid vehicle technologies and to demonstrate the commercial feasibility of these systems. Activities under the Act will require a great deal of road testing of existing and advanced vehicles. This testing is quite time consuming and costly due to the need for a) development and integration of complex instrumentation systems, b) transportation of vehicles to and from test tracks, c) track costs, d) per diem costs, e) lengthy test procedures which must often be repeated due to weather conditions, f) computer time for processing data, and g) appreciable amounts of engineering labor for data reduction and analysis. Throughout the course of the Act the road tests alone could amount to several hundreds of thousands of dollars or even millions of dollars depending upon the required number of tests.

One method for sharply reducing the time and cost of such tests is by development and use of analytical vehicle models. Once these models are developed, it is possible to carry out computer simulation runs and determine all the information that could be obtained in a road test, i.e., range, energy economy, acceleration capability, gradability, component and overall vehicle efficiency, etc. The runs can be carried out at a fraction of the cost of the road tests.

Successful development of a vehicle model requires detailed knowledge and analytical models of the vehicle's powertrain components including charger, battery, controller, motor, and gear train.

The scope of this investigation was limited to study of one of the above components, the battery. The objective was to test the relative accuracies of three previously proposed battery models in predicting battery performance. In particular it was desired to establish which of the three models gave the best prediction of electric vehicle battery output and corresponding electric vehicle range when subjected to selected driving patterns. The models of concern are referred to as the a) Fractional Utilization Model,⁽¹⁾ b) Shepherd Model,⁽²⁾

and c) Modified Hoxie Model.⁽³⁾ The driving patterns of concern are Schedules B,
C, and D, of SAE-J227a.⁽⁴⁾

SECTION II APPROACH

Approach to the problem consisted of both analytical and experimental investigations on an ESB EV-106 lead-acid battery. The analytical effort consisted of using the models to predict battery output when subjected to discharge regimes associated with the SAE driving cycles. The calculated outputs were then used to predict vehicle range in the manner described below. The experimental effort consisted of laboratory tests on the battery to determine actual outputs when subjected to the identical regimes as above. The measured outputs were then used to calculate range in the manner described below. A comparison was then made of actual and analytically predicted output to test accuracy of the models.

A. ANALYTICAL

Theoretical prediction of range for each of the models was carried out in the following manner. First, a current-time profile curve was obtained for each of the driving cycles. These profile curves were taken from prior road tests on the experimental Ripp-Electric vehicle (described in Section IV). Next, the current values from these profile curves were inserted into the models (with EV-106 constants) which were then solved to yield the number of driving cycles an EV-106 battery could complete to a defined end point. The range per cycle was then computed from the known velocity profile associated with the cycle. Finally, the total predicted range was taken as the product of number of cycles and range in kilometers (miles) per cycle.

B. EXPERIMENTAL

Experimental determination of range was carried out in the following manner. First, the same current-time profiles as above were taken for each of the driving cycles. Next, a computer program was written to have JPL's Automatic Charge-Discharge Controller and Data Processing System operate hardware (power supply and load) to discharge an EV-106 battery in accord with the given current-time profile. Then the test was performed to determine the number of cycles to a defined cutoff point. Finally, the range was computed in the same manner as above, i.e., product of number of cycles and range in kilometers (miles) per cycle.

SECTION III
DESCRIPTION OF MODELS

A. FRACTIONAL UTILIZATION MODEL

The Fractional Utilization Model was examined for its range prediction capability in a recent study by the General Research Co.⁽¹⁾ The model is based on the assumption that during each increment of time, Δt , a portion of the battery weight is depleted. As employed here, the term "depleted" means the expenditure of a given amount of discharge energy. This does not imply that the portion of the battery weight is permanently lost, as it can be subsequently recharged to supply additional energy. The portion depleted is:

$$\Delta W_B = \frac{P_j \Delta t}{E(P_j/W_B)} \quad (1)$$

where

ΔW_B = portion of battery depleted during Δt , kg (lbs)

P_j = battery power required during the jth interval, watts (product of average voltage and known current)

Δt = time of jth interval, hrs

$E(P_j/W_B)$ = specific energy density, watt-hrs/kg (watt-hrs/lb), which corresponds to the power density, P_j/W_B , watts/lb (this may be obtained from the manufacturer's plot of energy density vs. power density, or may be obtained experimentally).

The current profile during each driving cycle is approximated by a series of constant current steps, and the weight of the battery consumed during each step is computed by Eq. 1. The individual weights are then summed to give the total weight consumed per cycle. The number of cycles is obtained by dividing the total battery weight by the weight consumed per cycle. The range is taken as product of number of cycles and kilometers (miles) per cycle as above. The computational process is quite simple and can readily be carried out by means of a hand calculator.

B. SHEPHERD MODEL

The Shepherd Model was developed several years ago to characterize battery discharge data. It has, however, only recently been considered for use in electric vehicle applications. The model gives the relationship between battery voltages and current in accord with the following equation:

$$E = E_s - Ni - \left(\frac{Q}{Q-it} \right) Ki \quad (2)$$

where

E = battery operating voltage, volts

i = current, amps

= time, hrs

E_s = experimentally determined constant that corresponds to reference voltage, volts

N = experimentally determined constant that corresponds to internal resistance, ohms

K = experimentally determined constant that corresponds to polarization resistance, ohms

Q = experimentally determined constant that corresponds to battery capacity, amp-hrs.

Values of the constants E_s , N , K , and Q can be obtained either by the method given by Shepherd⁽²⁾ or by Taylor and Siwek.⁽³⁾ In this investigation, the constants were determined by the latter method, employing constant current discharge data supplied by ESB.⁽⁵⁾

The model is used to predict range in the following manner. First, the battery is assumed to be completely discharged when its terminal voltage reaches

3.00 volts at the highest discharge current. On this basis, we substitute the value of 3.00 volts for "E" in Eqn. 2. Next, the current profile during a driving cycle is approximated by a series of constant current steps as above. The product "it" is computed for each step and then summed for the cycle. The highest value of current from the above steps is then substituted for the value of "i" in Eqn. 2. The number of cycles "n" that the battery can deliver is then determined by substituting the above values in Eqn. 2 and solving for "n"

$$3.00 = E_s - N i_{\max} - \left(\frac{Q}{Q-nit} \right) K i_{\max} \quad (3)$$

Range is taken as the product of number of cycles and kilometers (miles) per cycle as above. The computational process is quite simple and can be carried out by means of a hand calculator.

C. MODIFIED FOXIE MODEL

The original Foxie Model⁽⁶⁾ was used to calculate the number of positive plates required for a battery to meet a specified load profile, such as given in Fig. 1. The model required discharge data in the form of time to cutoff at a specified voltage versus discharge rate. The required number of plates was determined by the following equation

$$P = \frac{A_1}{R_1} + \frac{A_2 - A_1}{R_2} + \frac{A_3 - A_2}{R_3} + \dots + \frac{A_n - A_{n-1}}{R_n} \quad (4)$$

where

P = number of plates required

$A_1, A_2, A_3 \dots$ = amperes for periods 1, 2, 3 etc

$T_1, T_2, T_3 \dots$ = time in hrs as indicated in Fig. 1

$R_1, R_2, R_3 \dots$ = amperes per positive plate for times T_1, T_2, T_3, \dots respectively (these currents are taken from the time to cutoff vs. discharge rate data referred to above).

A = CURRENT, AMPS

T = TIME, HRS

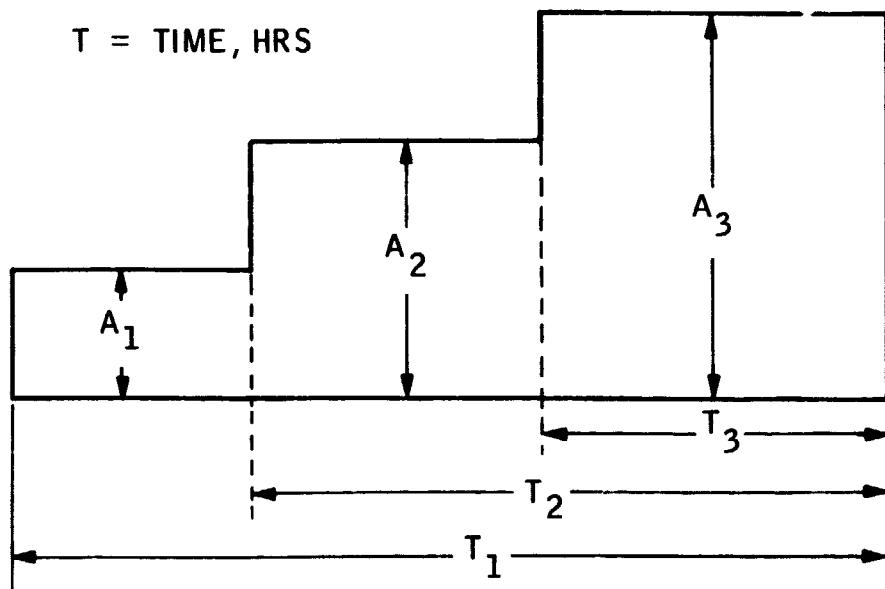

Figure 1. Typical Load Profile for Original Hoxie Model

A unique feature of the Hoxie Model is that it allows for capacity recuperation effects during periods of low current and open circuit as will subsequently be shown.

Another application of the Hoxie Model is to solve for the output time at known current and with a fixed number of plates. This requires an iterative computational process, as the time for complete discharge, T_1 , is unknown. One must first assume a value of T_1 , calculate the summation in Eqn. 4, and then compare the result with the selected number of plates. The process is repeated until the summation equals the selected number of plates.

This latter approach has served as a basis for development of the so-called Modified Hoxie Model given by Taylor and Siwek.⁽³⁾ The model is used to predict the output of a single battery, rather than a number of plates. The model requires discharge data (as above) that relates time to cutoff and discharge rate. This discharge data can be expressed analytically in terms of the Shepherd constants given as follows:

$$i = \frac{\Delta E t_c + Q(N + K)}{2N t_c} + \sqrt{\frac{(\Delta E t_c + NQ + KQ)^2}{4N^2 t_c^2} - \frac{Q\Delta E}{N t_c}} \quad (5)$$

where

i = current, amps

t_c = time to cutoff to a given voltage, hrs

ΔE = $E_s - E_c$, volts (E_s is a Shepherd constant and E_c is cutoff voltage, 3.00 volts in the case of EV-106 batteries)

Q = Shepherd constant as above

N = Shepherd constant as above

K = Shepherd constant as above

The model states that the battery is completely discharged when the sum of the terms on the right-hand side of the following equation equals one:

$$1 = \frac{A_1}{R(t_1)} + \frac{A_2 - A_1}{R(t_2)} + \frac{A_3 - A_2}{R(t_3)} \dots + \frac{A_n - A_{n-1}}{R(t_n)} \quad (6)$$

where

1 = one complete battery

$A_1, A_2, A_3 \dots$ = amperes for periods 1, 2, 3 etc in Fig. 2

$t_1, t_2, t_3 \dots$ = time in hrs as indicated in Fig. 2

$R(t_1), R(t_2) \dots$ = amperes per battery for times $t_1, t_2, t_3 \dots$ respectively
 $R(t_3)$ (these currents are computed from Eqn. 5).

A = CURRENT, AMPS

t = TIME/HRS

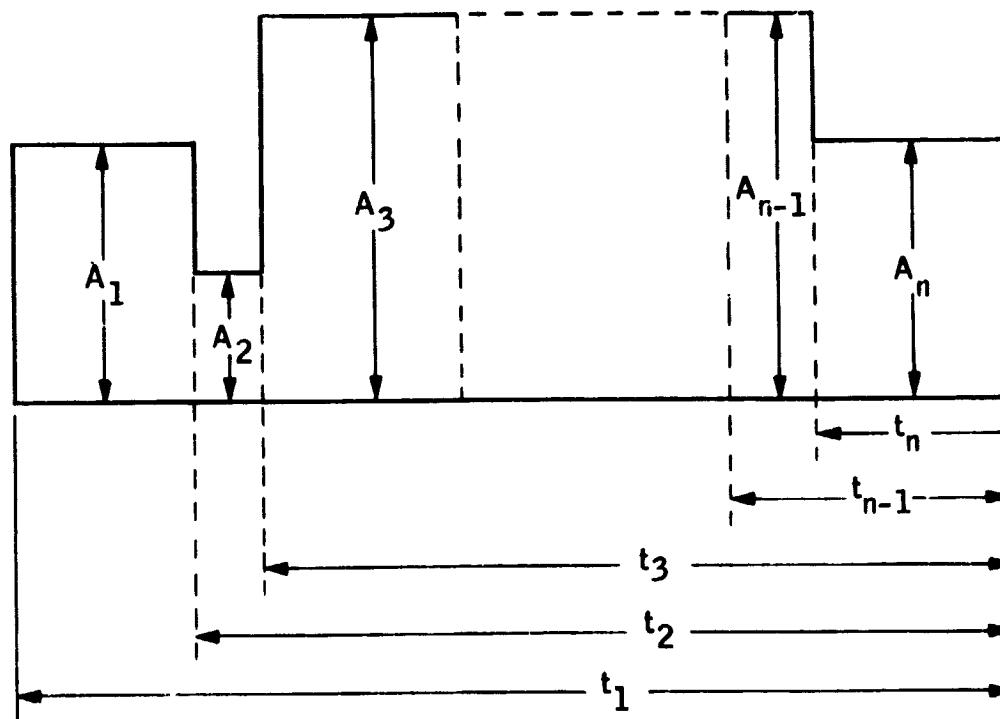

Figure 2. Generalized Load Profile for Modified Hox.e Model

Eqn. 6 is solved by the iterative process described above, i.e., by assuming a value of t_1 , computing the sum, and then repeating the process if the sum is greater or less than one.

Due to the lengthy calculations, it was necessary to set up a computer program to solve Eqn. 6 for the total operating time and number of driving cycles. A complete description of the program labeled Program "VCTIR" is given in Appendix A-1. Input parameters are given as currents and times of the driving cycles as well as values of the Shepherd constants. Output of the program is total operating time and number of driving cycles that the battery can deliver. Range is again taken as product of number of driving cycles and kilometers (miles) per cycle. It is well to point out that now that the program has been set up, it can be used not only to predict the effect of type of driving cycle on range, as

77-29

is done herein, but also the effect of type of battery on range (by merely inserting the appropriate Shepherd constants for the battery of interest).

SECTION IV

DRIVING CYCLES AND CURRENT PROFILES

A schematic of an SAE J227-a driving cycle is given in Fig. 3. The cycle is broken down into five periods consisting of an acceleration period (t_a), a cruise period (t_{cr}), a coast period (t_{co}), a brake period (t_b), and an idle period (t_i). Time and maximum speed attained during the acceleration period are specified in the SAE procedure. Time and speed of the cruise period are specified in the procedure. Time of the coast period is determined experimentally on the vehicle. Time of the brake period and zero speed at the end of this period are specified in the procedure. Time and zero speed during the idle period are also specified in the procedure.

Figures 4, 5, and 6 give the velocity profiles of the Ripp-Electric Vehicle while on Driving Schedules "B", "C", and "D" of SAE-J227a. Maximum cruise speeds for Schedules "B", "C", and "D" are noted to be 32.2, 48.3, and 72.4 km/hr (20, 30, and 45 mph) respectively. Total operating times on Schedules "B", "C", and "D" are noted to be 72, 80, and 122 sec/cycle respectively. Distance traveled during each cycle may be computed by taking the sum of the product of average speed and indicated times during each segment of the cycle. For Schedules "B", "C", and "D" the computed distances are 0.3377, 0.5389, and 1.5451 km/cycle (0.2099, 0.3349, and 0.9603 miles/cycle) respectively.

Road tests established how battery currents varied during the course of a driving cycle. During acceleration, for example, the current was found to increase in an essentially linear manner with time. At the completion of the acceleration period, the current dropped sharply to a lower level and maintained this level during the cruise period. At the completion of the cruise period, the current dropped sharply to zero and maintained this value during the periods of coast, brake, and idle.

Figures 7, 8, and 9 give the current profiles experienced by the Ripp-Electric Vehicle battery during the course of vehicle operation on driving schedules "B", "C", and "D" of SAE-J227a. Figure 7 gives the profile for schedule "B". It is noted therein that the peak current attained after 19 sec of acceleration is 100 amp and that the steady current during the 19 sec of cruise is 30 amp.

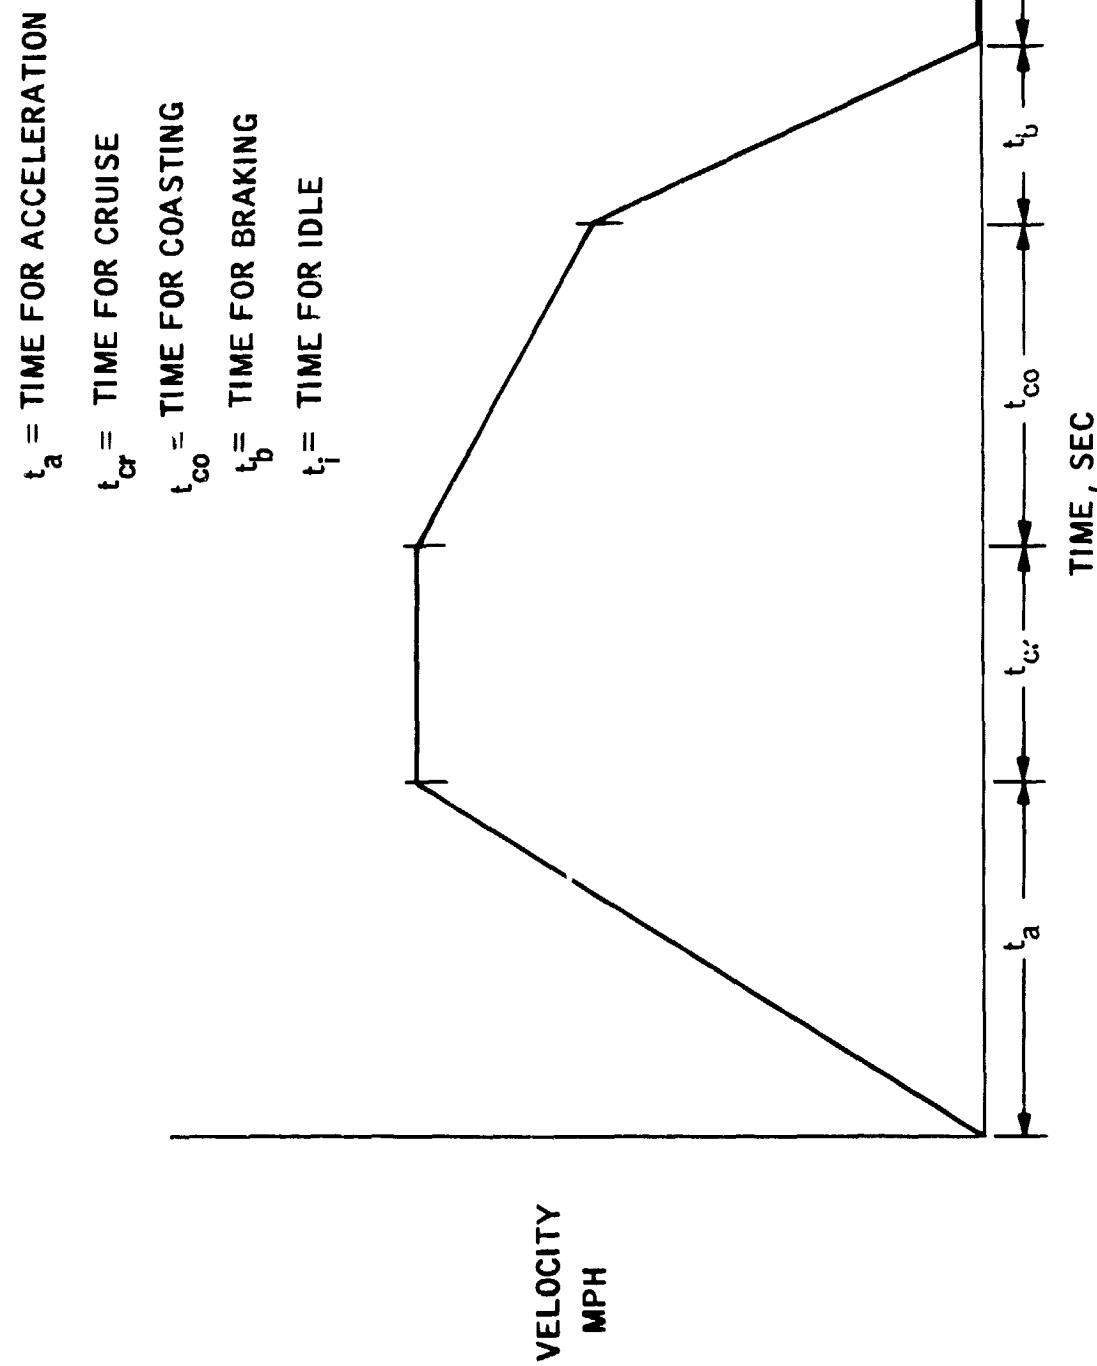

Figure 3. Schematic of SAE-J227a Driving Cycle

77-29

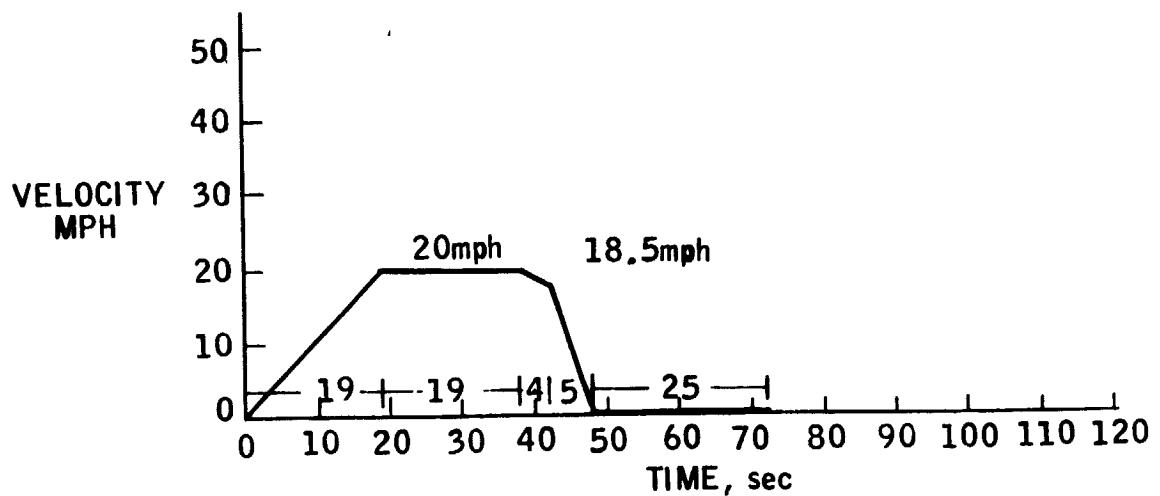

Figure 4. Velocity Profile of Ripp-Electric Vehicle on Schedule "B"

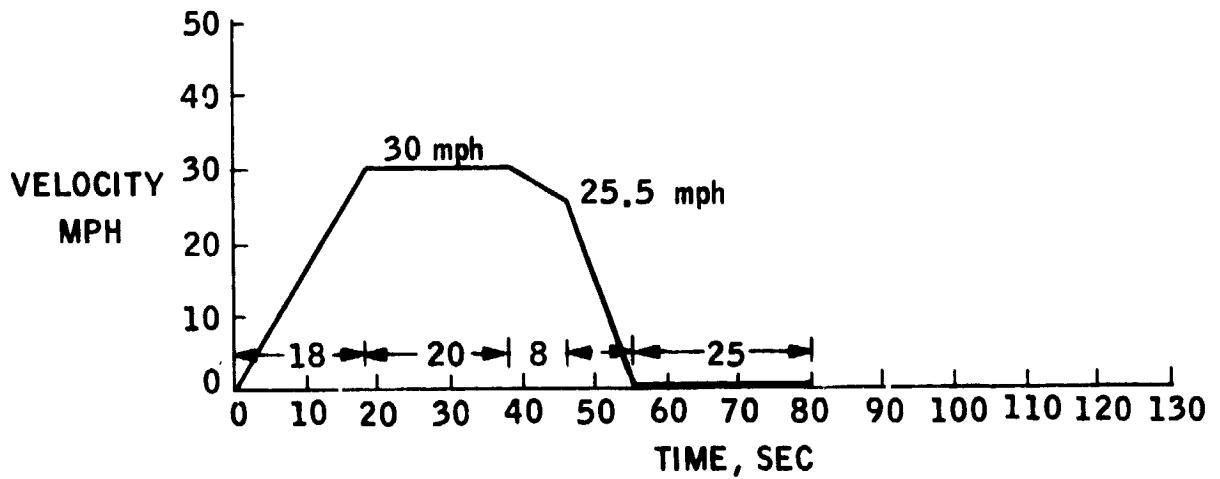

Figure 5. Velocity Profile of Ripp-Electric Vehicle on Schedule "C"

77-29

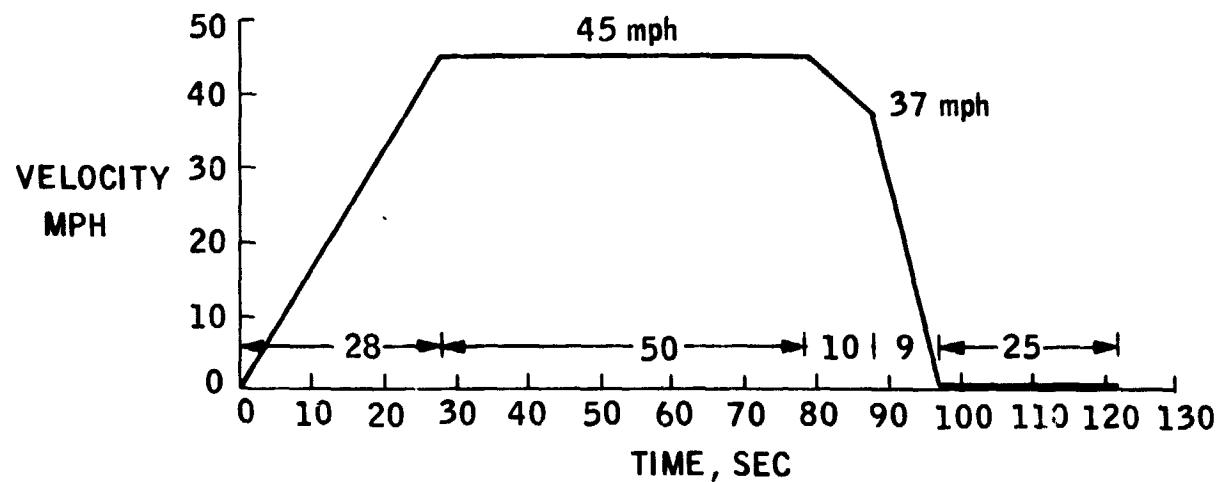

Figure 6. Velocity Profile of Ripp-Electric Vehicle on Schedule "D"

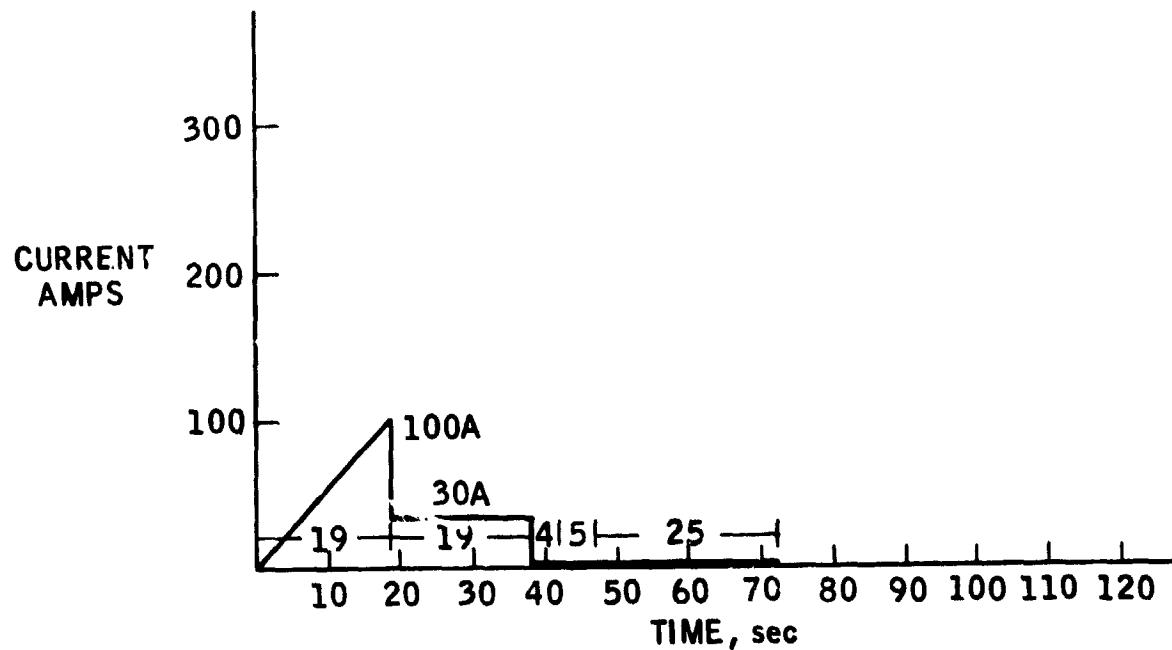

Figure 7. Current Profile of Ripp-Electric Vehicle Battery on Schedule "B"

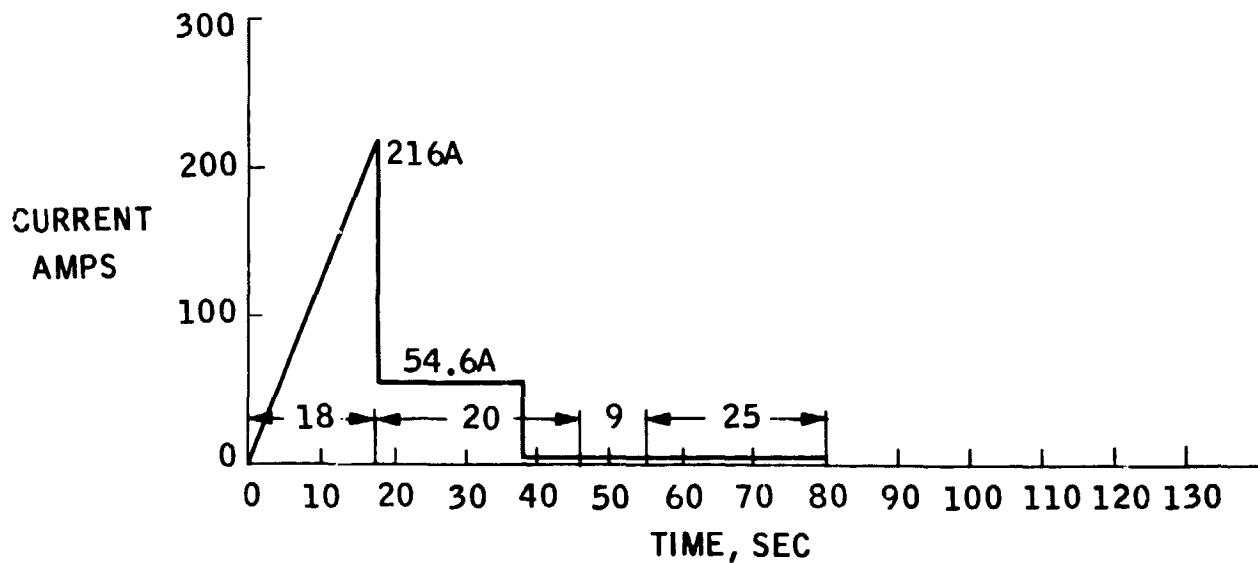

Figure 8. Current Profile of Ripp-Electric Vehicle
Battery on Schedule "C"

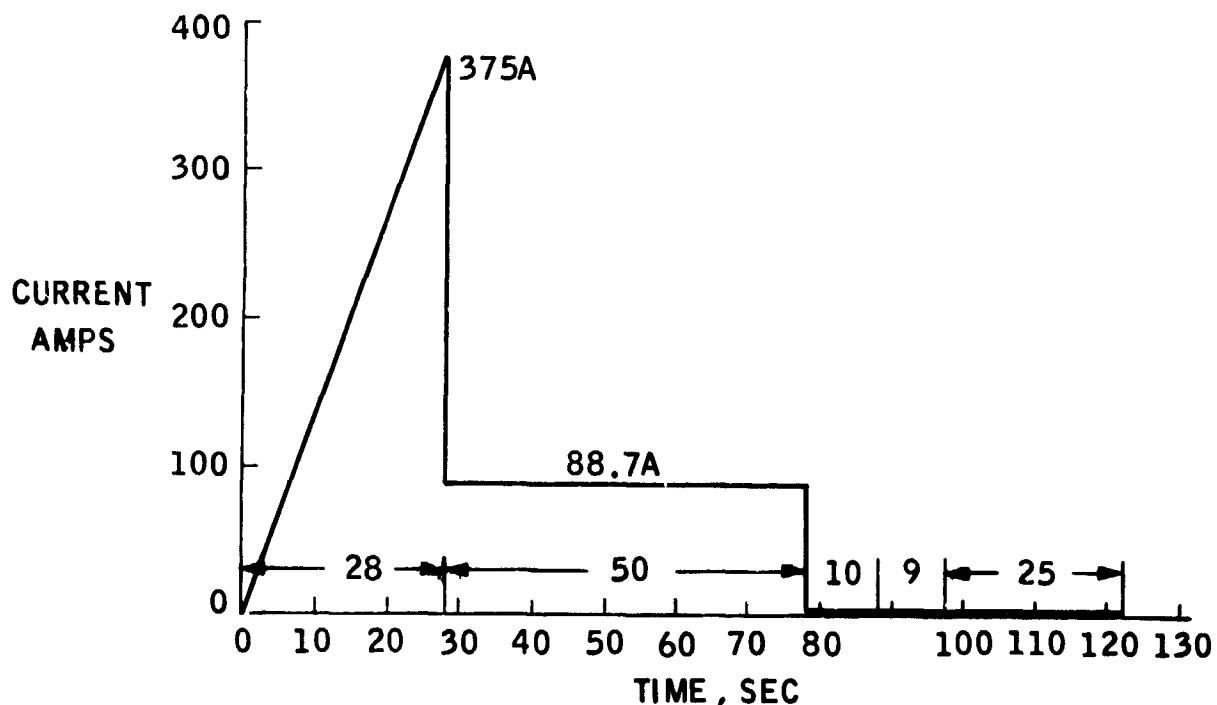

Figure 9. Current Profile of Ripp-Electric Vehicle
Battery on Schedule "D"

Figure 8 gives the profile for schedule "C". It is noted therein that the peak current attained after the 18 sec of acceleration is 216 amp and that the steady current during the 20 sec of cruise is 54.6 amp. Figure 9 gives the profile for schedule "D". It is noted therein that the peak current attained after 28 sec of acceleration is 375 amp and that the steady current during the 50 sec of cruise is 88.7 amp.

Input data format for the models described herein requires constant current, rather than linearly varying current with time. For this reason, the linearly varying current ramp during acceleration is approximated by a series of step currents as indicated in Figs. 10, 11, and 12 for schedules "B", "C", and "D", respectively. For schedule "B" in Fig. 10, the 19 sec acceleration ramp is divided into two equal periods of 9.5 sec each. During the first 9.5 sec period the current is specified as 25 amp or 1/4 of the peak current of 100 amp. During the second 9.5 sec period the current is specified as 75 amp or 3/4 of the peak current of 100 amp. In this manner, the average current is the same as for the

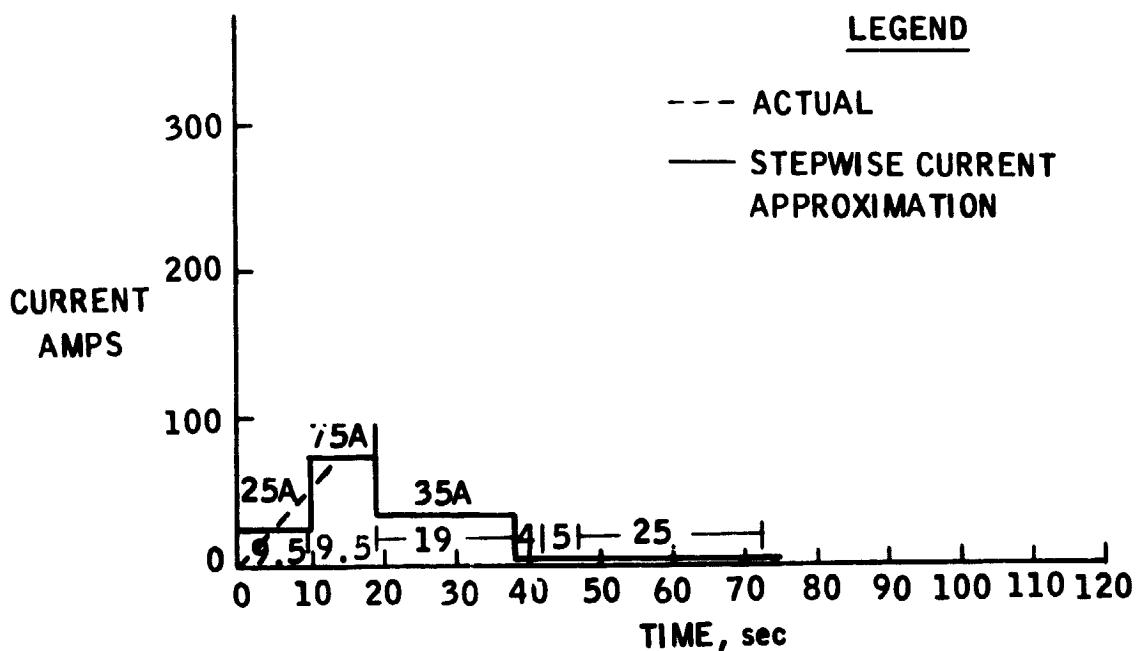

Figure 10. Stepwise Current Approximation for Ripp-Electric Vehicle Battery on Schedule "B"

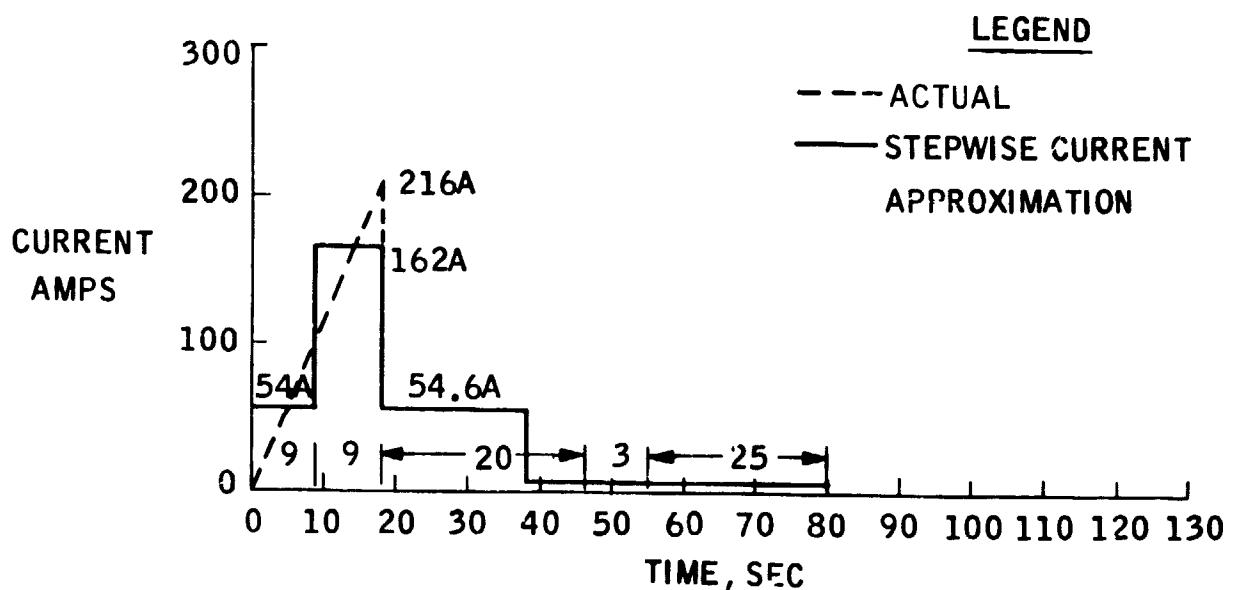

Figure 11. Stepwise Current Approximation for Ripp-Electric Vehicle Battery on Schedule "C"

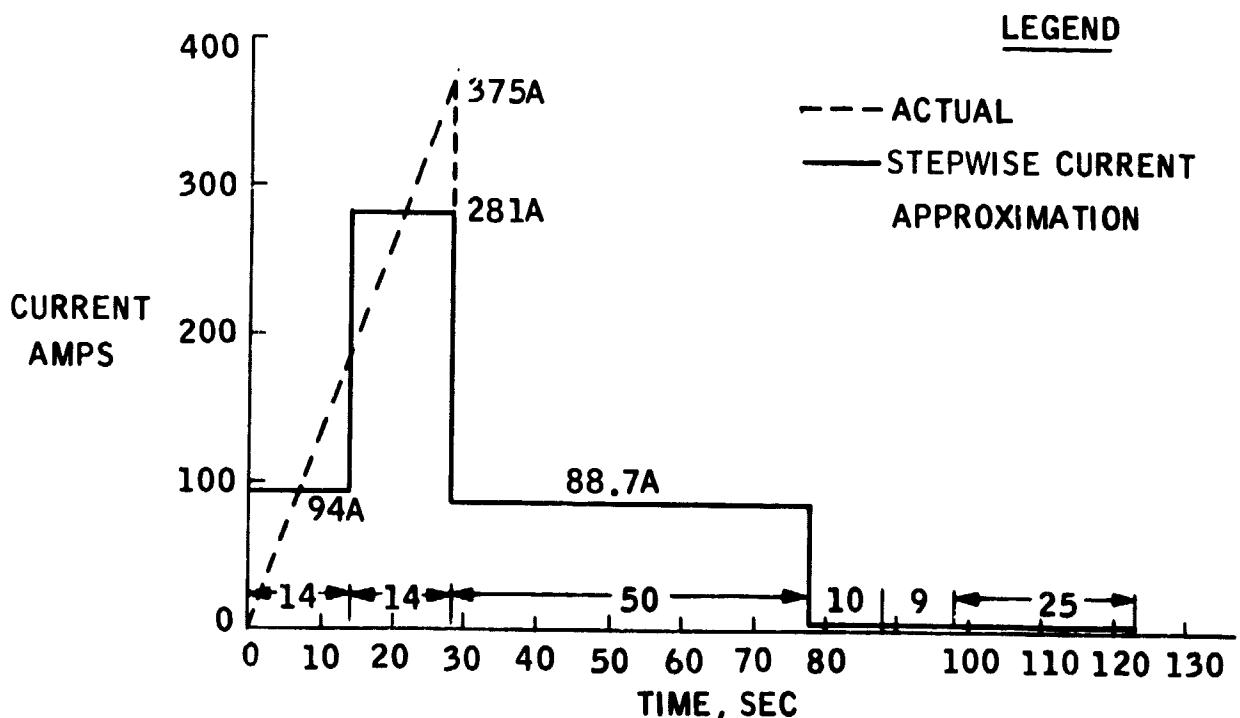

Figure 12. Stepwise Current Approximation for Ripp-Electric Vehicle Battery on Schedule "D"

case where the current increases linearly to 100 amp over a 19 sec period. Similarly for schedule "C" in Fig. 11 the 18 sec acceleration ramp is divided into two 9 sec periods, during the first of which the current is 54 amp, and during the second of which the current is 162 amp. Similarly for schedule "D" in Fig. 12, the 28 sec acceleration ramp is divided into two 14 sec periods, during the first of which the current is 94 amp, and during the second of which the current is 281 amp.

SECTION V
INPUT DATA FOR MODELS

Range prediction via each of the models generated the following input data for cycle and EV-106 parameters.

A. FRACTIONAL UTILIZATION MODEL

- (1) Weight of battery = 28.4 kg. (.62 lbs)
- (2) Average assumed discharge voltage = 5.65 volts
- (3) Step current profiles (as given in Figs 10 through 12)
- (4) Energy density vs. power density (from manufacturers' data given in Fig. 13)⁽⁵⁾
- (5) Range per cycle = 0.3377 km/cycle (0.2099 mi/cycle for schedule "B")
= 0.5389 km/cycle (0.3349 mi/cycle for schedule "C")
= 1.5451 km/cycle (0.9603 mi/cycle for schedule "D").

B. SHEPHERD MODEL

- (1) E_{cutoff} = 3.00 volts (this represents manufacturers' recommended cutoff; the value can, of course, be varied)
- (2) E_s = 6.15 volts
- (3) Q = 170 amp-hr
- (4) N = -0.0013 ohms
- (5) K = 0.0038 ohms
- (6) Step current profiles (as given in Figs. 10 through 12)

77-29

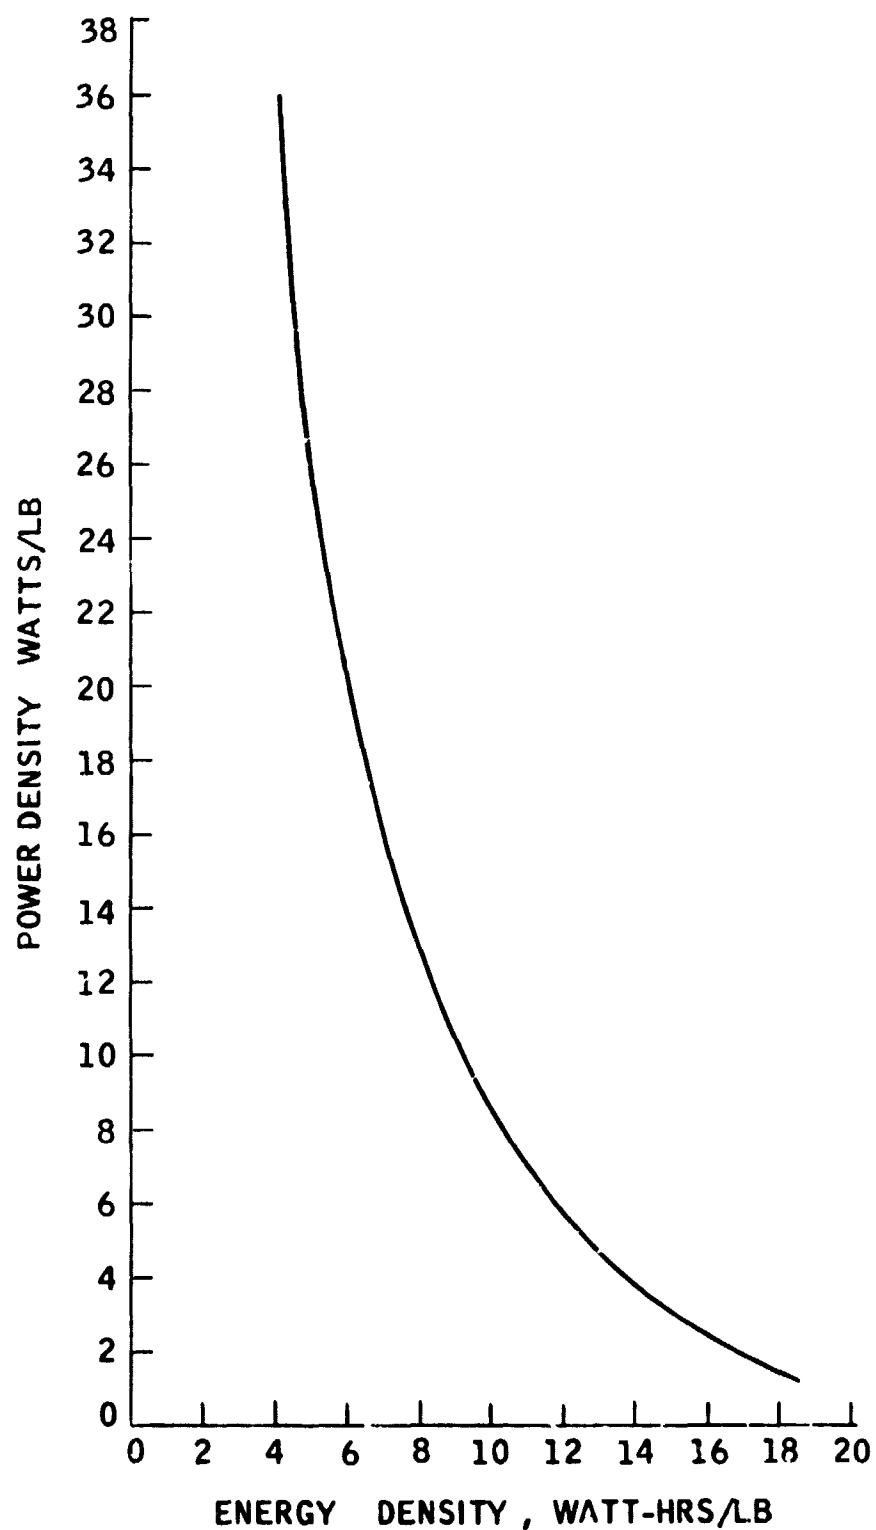

Figure 13. Manufacturers' Supplied Performance Data on EV-106 Battery⁽⁵⁾

- (7) Range per cycle = 0.3377 km/cycle (0.2099 mi/cycle for schedule "B")
 0.5389 km/cycle (0.3349 mi/cycle for schedule "C")
 1.5451 km/cycle (0.9603 mi/cycle for schedule "D").

C. MODIFIED HOXIE MODEL*

(1) $E_s = 6.15$ volts

(2) $\Delta E = E_s - E_{cutoff} = 6.15$ volts - 5.25 volts = 0.90 volts

(3) $Q = 170$ amp-hr

(4) $N = -0.0013$ ohms

(5) $K = 0.0038$ ohms

(6) Peak current at end of acceleration ramp

100 amps for schedule "B"

216 amps for schedule "C"

375 amps for schedule "D"

(7) Time duration of acceleration ramp

19 sec for schedule "B"

18 sec for schedule "C"

29 sec for schedule "D"

(8) Number of steps in acceleration ramp

2 for schedules "B", "C", and "D"

(9) Current during cruise period

35.0 amps for schedule "B"

54.6 amps for schedule "C"

88.7 amps for schedule "D"

*NOTE: A computer program designated "Program VCTIR" was set up to solve Eqn. 6 for a) time to cutoff, and b) number of cycles using the above or any other values of cycle and battery parameters. This program is described in Appendix A-1.

- (10) Time duration of cruise period
19 sec for schedule "B"
20 sec for schedule "C"
50 sec for schedule "D"
- (11) Time duration at open circuit (coast time + brake time + idle time)
34 sec for schedule "B"
42 sec for schedule "C"
44 sec for schedule "D"
- (12) Range per cycle = 0.3377 km/cycle (0.2099 mi/cycle for schedule "B")
0.5389 km/cycle (0.3349 mi/cycle for schedule "C")
1.5451 km/cycle (0.9603 mi/cycle for schedule "D")

SECTION VI
DRIVING CYCLE LABORATORY SIMULATION TESTS

A computer program operating in a real-time operating system environment on JPL's Automatic Charge-Discharge Controller and Data Processing System (ACDCDPS) simulates various driving cycle current profiles according to SAE 227A requirements. Parameters input during the initial execution of this program predetermine the driving schedule that will be simulated and the voltage limit for termination of the test.

The program transmits data to a relay-output card and a resistance output card, both located in an HP 6941B Multiprogrammer Extender (Digital Input/Output Multiplexor Subsystem) within the ACDCDPS. The relay-output card operates a 400A contactor that controls the two states of the battery under test; discharge or open circuit. The resistance output card controls the output current of a resistance-programmable, constant current HP 6466C DC Power Supply through the battery and a diode load network. An HP-supplied subroutine is entered at several locations in the program to suspend execution. The resulting delays in execution control the resistance card output and relay output with respect to time.

An operator enters the time delays in units of 10-milliseconds and two octal integers that relate to the peak current during acceleration and constant current during cruise, respectively. Then, an additional entry to display the values entered, start the testing, or stop program execution entirely.

Battery voltage is measured (1) approximately 30 milliseconds before the start of the acceleration current profile, (2) approximately 30 milliseconds after the peak current is reached at the end of the acceleration current ramp, and (3) again approximately 30 milliseconds after the end of the constant current cruise period.

A diagram of the ACDCDPS, the test layout, and program listing, designated as "BTEST", appear in Appendix A-2.

The current profiles to which the EV-106 battery was subjected are given in Figs. 7, 8, and 9 for schedules "B", "C", and "D" respectively.

The batteries were charged overnight at constant current until specific gravities were in the range of 1.29 to 1.30 at 90°F. Discharge was carried out at ambient temperature near 70°F.

SECTION VII
RESULTS

Table 1 gives a comparison of the analytically predicted driving cycles and range with the experimentally determined driving cycles and range as simulated in the laboratory with an EV-106 battery. The first column designates the type of predictive model and also the experimental result. The next two columns give both predicted and actual number of cycles and corresponding range when subjected to the current profile of Schedule "B". The next two columns give both predicted and actual number of cycles and corresponding range when subjected to the current profile of Schedule "C". The last two columns give both predicted and actual number of cycles and corresponding range when subjected to the current profile of Schedule "D". Experimentally determined battery voltages during the course of these tests are given in Appendix A-3.

Experimentally determined amp-hr outputs for Schedules "B", "C", and "D" were 173.2 AH, 155.0 AH, and 131.5 AH, respectively.

Table 1. Range Predicted by Models Compared to Laboratory Simulation

| Model | Schedule B | | | Schedule C | | | Schedule D | | |
|---------------------------|------------|-------------------|------------|-------------------|------------|-------------------|------------|-------------------|------------|
| | No. Cycles | Range, km (mi) | No. Cycles |
| 1) Fractional Utilization | 329 | 110.7 (68.8) | 127 | 68.4 (42.5) | 31 | 47.9 (29.8) | | | |

SECTION VIII SUMMARY AND CONCLUSIONS

Inspection of Table 1 indicates that the Modified Hoxie model gives the highest predicted range and number of driving cycles. This result is explained by the fact that this model takes into account battery recuperative effects while the other models do not take these effects into account. Further, it is noted that the experimental results agree very favorably with those predicted by the Modified Hoxie model. For Schedules C and D, the model overestimates the range by 2% and 14%, respectively, and for Schedule B the model underestimates range by 2%. The Shepherd model predicts somewhat lower ranges than actual although the discrepancy is not too large (from 6 to 10% less depending on the Schedule). The Fractional Utilization model yields appreciably lower ranges than actual (from 11 to 37% less depending on the Schedule) and is the least accurate of the models.

Based on the above, it appears that the Modified Hoxie model may be used with high degree of confidence in predicting vehicle range. Accuracy of the model is 97 to 98% in most cases and 86% in the worst case.

Range prediction via the Modified Hoxie model is quite simple and rapid once the computer program has been written to solve the model's iterative calculations. Required inputs are simply: a) maximum current at end of acceleration and during cruise, b) the specified times associated with the various segments of the SAE J227a driving cycles, and c) the Shepherd constants for the battery of interest. This input data has already been obtained in the case of the Ripp-Electric vehicle with EV-106 batteries. The data may be obtained quite readily for other vehicles and batteries by short-term tests on these vehicles and batteries. Once the input data is entered, the computer solves for number of cycles and range in a matter of only a few seconds.

SECTION IX
RECOMMENDED FUTURE EFFORTS

Having demonstrated a high degree of accuracy of the Modified Hoxie model, it can now be used in a number of significant applications. One of these would involve range prediction for the Ripp-Electric Vehicle on the SAE driving schedules with batteries other than the EV-106's. Amongst the other batteries to be examined are other types of lead-acid batteries as well as Ni-Zn, Ni-Fe, Zn-Cl₂, Zn-Br₂, Fe-Air, Na-S, and LiAl-FeS batteries. Another application would involve range predictions for other electric vehicles on the SAE driving schedules with the EV-106 and other batteries described above. Another application would involve range predictions for advanced electric vehicles that remain yet on the drawing board. These predictions could be carried out for the SAE driving schedules with EV-106 and other batteries described above. In this case, the currents during acceleration and cruise would be estimated from overall vehicle design models.

Results of the above efforts will help to implement in a timely and cost-effective manner the provisions of the Electric and Hybrid Research and Development Act of 1976 (Public Law 94-413), dealing with development of advanced electric vehicles. On this basis, it is strongly recommended that the proposed efforts be initiated as soon as possible.

APPENDIX A-1

- Description of Program "VCTIR"
- Listing of Program VCTIR

APPENDIX A-1

DESCRIPTION OF PROGRAM VCTIR

Program VCTIR calculates the number of driving cycles and the total elapsed time for a battery (having specified battery constants) to be reduced to its cutoff voltage. The method used is to divide each cycle into intervals of constant amperage levels and calculate the following sum over all cycles:

$$S_2 = \frac{A_1}{I_1} + \frac{A_2 - A_1}{I_2} + \frac{A_3 - A_2}{I_3} + \dots + \frac{A_N - A_{N-1}}{I_N}$$

where $A_1, A_2, A_3, \dots, A_N$ are the amperage levels over all cycles, and $I_1, I_2, I_3, \dots, I_N$ are the values of the current for which the battery will reach its cutoff voltage in time $T_1, T_2, T_3, \dots, T_N$. T_1 is the total time for all cycles, $T_2 = T_1 - (\text{time duration of level } A_1)$, $T_3 = T_2 - (\text{time duration of level } A_2)$, ... and T_N is the time duration of the last amperage level. The value of T_1 for which $S_2 = 1$ is the theoretical time for the battery to reach its cutoff voltage for the specified driving cycle.

The driving cycle consists of the following three parts:

- 1) A discharge ramp from zero amps to some level A_{\max} amps in time TR hours. (A linear ramp is approximated by $NINC$ rectangular steps.) The first and last steps are $AINC$ amps in height, and the intervening steps are $ASTEP$ amps in height, where $ASTEP = AH/NINC$ amps and $AINC = ASTEP/2$ amps. The time duration of each step in the ramp is $TINC = TR/NINC$ hours.
- 2) A constant discharge (cruise) amperage level of AL amps for a time duration of TDL hours.
- 3) An open circuit period of TO hours.

The program calculates the value of T_1 for which $S_2 = 1$, using successive approximations. That is, a guess is made for T_1 , then S_2 is calculated for that T_1 . If $S_2 = 1$ somewhere within the last cycle for that value of T_1 , the calculation is finished. Otherwise, a better guess is made for T_1 , the sum S_2 is again calculated, and so on until the sum $S_2 = 1$.

The program listing is given on the following pages.
